CHAPTER 1

Geoepidemiology of Sarcoidosis

PILAR BRITO-ZERÓN, MD, PHD • BELCHIN KOSTOV, PHD •
ROBERT PHILLIP BAUGHMAN, MD • MANUEL RAMOS-CASALS, MD, PHD

INTRODUCTION

Sarcoidosis, a systemic disease of unknown etiology characterized by the development of noncaseating epithelioid cell granulomas, often affects young adults aged between 20 and 50 years.¹ Sarcoidosis is a systemic disease with a heterogeneous clinical presentation, although clearly dominated by thoracic involvement. Epidemiologically, sarcoidosis is a rare disease with a significant influence of ethnicity and environmental factors that play a key role in the phenotypic expression of sarcoidosis²; notably, the three organs most frequently affected (the lungs, skin, and eyes) are in direct contact with the external environment.³

The rarity of sarcoidosis, together with the key role of ethnic and geoepidemiological factors, means that the larger the population analyzed, the better the characterization of clinical expression, and the more likely the findings will reflect the real population affected by the disease. Big data–driven research is a key instrument that may help provide a high-definition picture of infrequent and heterogeneous diseases such as sarcoidosis.⁴ This chapter updates the main geoepidemiological features associated with sarcoidosis using the merged data of 117,175 patients with sarcoidosis included in large series (>100 patients) reported in the PubMed library.^{5–103}

PREVALENCE AND INCIDENCE

Table 1.1 summarizes the prevalence and incidence rates of sarcoidosis country per country. The highest rates are reported in Northern Europe, the United States, and India (Fig. 1.1A and B): the estimated incidence in Europe ranges between 1 and 15 cases per 100,000 inhabitants, with significantly higher rates in northern countries.¹⁰⁴ In the United States, sarcoidosis is more common in Black/African Americans (BAAs).¹⁰⁵ In the largest reported US series,⁵⁶ the highest incidence

rate was reported in BAA people (17.8 per 10⁶ inhabitants) compared with Whites, Hispanics, and Asians (8.1, 4.3, and 3.2, respectively). In Detroit, Rybicki et al.¹⁰⁶ reported an incidence rate of 35.5 in BAA versus 10.9 in Whites, while two Navy studies^{107,108} reported rates of 47.8–81.8 for BAA compared with 4.4–7.6 for Whites. Similar differences are reported for the prevalence per 100,000 inhabitants in US studies (64–141 for BAAs, 7–50 for Whites, 22 for Hispanics, and 19 for Asians).^{56,109,110} Out of the United States, people from India living in London or Singapore had the highest rates of incidence and those from East Asia living in the United States or Singapore the lowest rates in comparison with the other ethnicities living in the same geographical area. In multiethnic cohorts from London, with a differing ethnic distribution than the US cohorts, the highest rates were reported in West Indian (incidence of 58, prevalence of 183 cases per 10⁶ inhabitants) and Irish (incidence 21, prevalence 155) people in comparison with UK-born people (incidence 4, prevalence 27).^{111,112} Benatar found a prevalence among Blacks of 23.2 per 10⁶ inhabitants compared with Whites (3.7) and mixed race (11.6)¹¹³ people in Cape Town, while Anantham et al.¹¹⁴ reported a yearly incidence of 0.56 per 10⁶ inhabitants in Singapore, with clearly different figures for Indian (4.57), Malaysian (1.30), and Chinese (0.23) people.

AGE AND GENDER

Our big data analysis confirmed that sarcoidosis affects both sexes but with a slight predominance of females and is mainly diagnosed in the fourth and fifth decades of life, with a mean age at diagnosis of 41 years and 52% of women affected in our merged data analysis (Table 1.2). Specific analysis of cohorts from the three main geographical areas (United States, Europe, and Asia) found significant differences, especially in

gender distribution (Fig. 1.2): the highest percentage of females was reported in Asian studies (65%) and the lowest in European (49%), while the youngest age at diagnosis was found in the US studies (39.8 years).

Ethnicity may influence the mean age at diagnosis and the gender ratio, as has been reported by US studies in BAA patients,⁵⁶ who developed the first sarcoidosis-related symptoms at an earlier age than Whites.^{49,115} A classification of the reported cohorts according to the predominant ethnicity (>50%) found that the frequency of women affected was significantly higher in predominantly BAA cohorts than in Asian and White predominant cohorts (67% vs. 64% vs. 51%, respectively, $P < .001$) (Fig. 1.3); the higher the frequency of BAA patients included in a cohort, the greater the number of females, while the higher the frequency of White patients, the higher the number of males. A geographical gradient for the gender ratio is observed in studies from countries located between parallels 30 and 45

(Mediterranean countries, Japan, and Southern United States), in which two-thirds of patients with sarcoidosis are women, while in the north of Europe and India more than half the patients are men.

ETHNICITY

Although sarcoidosis affects all ethnicities, it is more frequently reported in Whites. According to our big data, ethnicity was detailed in 25,951 patients: 15,443 (59.5%) were classified as White, 6520 (25.1%) as BAA, 2985 (11.5%) as Asian, and 1003 (3.9%) as other ethnicities (Table 1.2) (Fig. 1.4). There are large ethnicity-driven variations in the frequency, epidemiological and clinical expression, and outcomes, although the differences should be always evaluated taking into account socioeconomic disparities that could modify the level of exposure to potential environmental toxins.¹⁰⁴

How Ethnicity Influences the Clinical Presentation

The differing clinical expression of sarcoidosis according to ethnicity was first reported in the 1960s.^{116,117} Most recent studies have been carried out in multiethnic populations and have reported a differing clinical expression when comparing between different ethnicities. The largest US studies comparing the two

predominant ethnicities (BAAs vs. Whites) reported a higher frequency of advanced radiographic stages of sarcoidosis, low FVC% predictive values, and more organs involved in BAA patients, including a higher frequency of ocular, liver, bone marrow, extrathoracic lymph nodes, and skin (other than erythema nodosum) sarcoidosis, while splenic involvement and hypercalcemia were more frequent in Whites. In addition, BAA patients

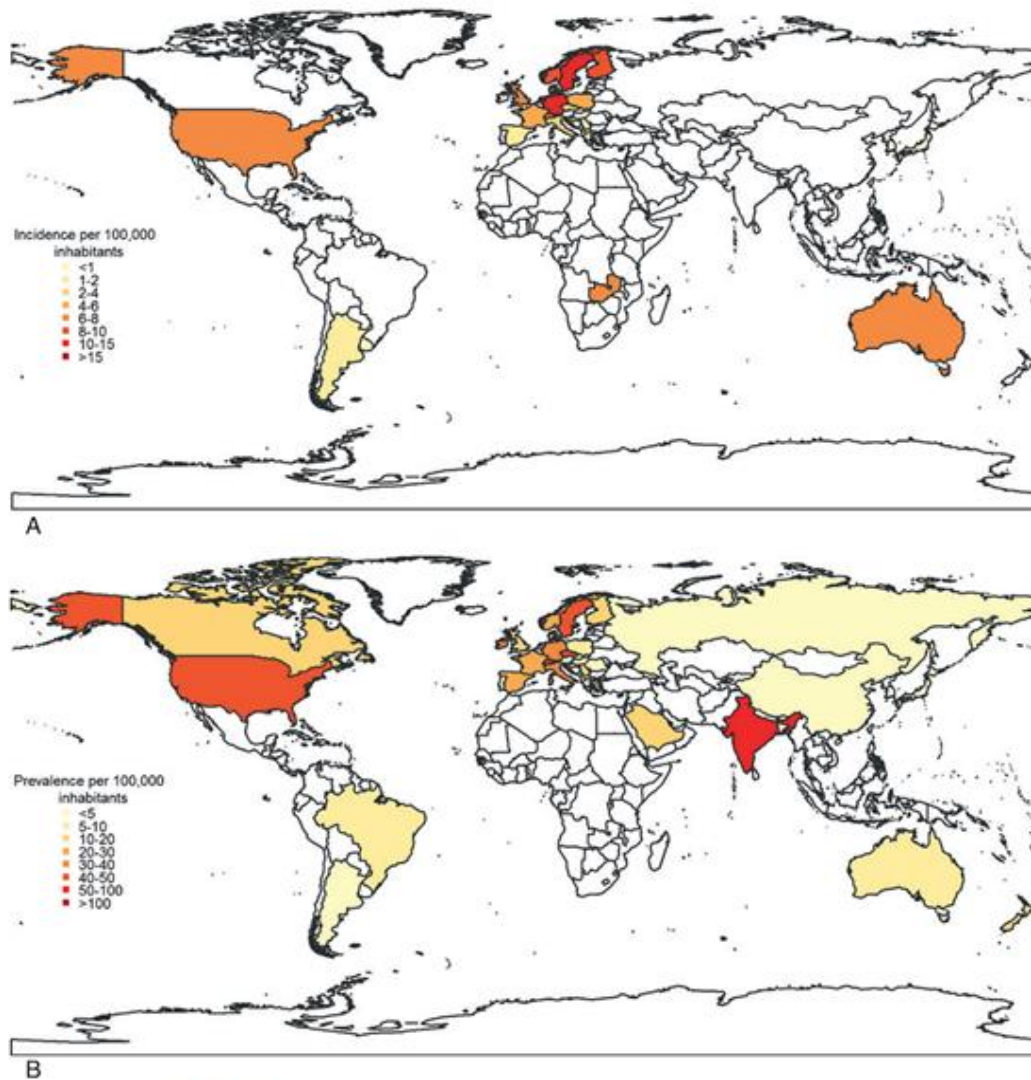

FIG. 1.1 Worldwide frequency of sarcoidosis: (A) incidence and (B) prevalence.
